*Accepted papers* are articles in press that have gone through due peer review process and have been accepted for publication by the Editorial Board of the *Serbian Archives of Medicine*. They have not yet been copy-edited and/or formatted in the publication house style, and the text may be changed before the final publication. Although accepted papers do not yet have all the accompanying bibliographic details available, they can already be cited using the year of online publication and the DOI, as follows: the author’s last name and initial of the first name, article title, journal title, online first publication month and year, and the DOI; e.g.: Petrović P, Jovanović J. The title of the article. Srp Arh Celok Lek. Online First, February 2017.

When the final article is assigned to volumes/issues of the journal, the Article in Press version will be removed and the final version will appear in the associated published volumes/issues of the journal. The date the article was made available online first will be carried over.

Combined laparoscopic–endoscopic “rendez-vous” procedure in a case of gastric schwannoma in a toddler

Комбинована лапароскопско-ендоскопска „рандеву“ процедура у случају гастричног шванома код малог детета

SUMMARY

Introduction Schwannomas are rare benign tumors of the gastrointestinal tract. Despite the differences in features of schwannomas located in the stomach as opposed to peripheral or soft tissue schwannomas, their immunohistochemical characteristics are the same. We present a case of a 14-month-old boy with a gastric tumor who underwent a combined laparoscopic-endoscopic resection surgery, followed by gastric schwannoma diagnosis.

Case outline The patient was admitted to our pediatric hospital with a fever of unknown origin. Endoscopy, performed after recurrent hematemesis, revealed an ulcer in the gastric antrum. At the four-week follow-up, gastrointestinal and microscopic findings were normal. Two weeks later, a flank mass in the antrum was detected by an ultrasound examination. A new gastroscopy and CT scan confirmed the presence of a tumor-like mass, 5 cm in diameter. A combined laparoscopic-endoscopic polypectomy was performed with a necessary conversion for complete resection of tumor. The initial histological findings were consistent with a gastrointestinal stromal tumor. Due to this tumor’s rarity in childhood, the paraffin-embedded tissue samples were referred for a second opinion. Histological and immunohistochemical characteristics of the tumor made the gastrointestinal stromal tumor diagnosis unlikely and consistent with a completely resected gastric schwannoma. No recurrence of the disease occurred during the seven-year follow-up.

Conclusion Combined laparoscopic-endoscopic surgery is a feasible and effective treatment for large gastric tumors that cannot be excised endoscopically. Schwannoma should be included in the differential diagnostic consideration of gastric tumor lesions even in childhood.

САЖЕТАК

Увод Шваноми су ретки бениги тумори гастроинтестинализног тракта. Без обзира на разлике у особинама шванома у желудцу и шванома периферних нерава, њихове имунохистохемске карактеристике су исте. Представљамо четиримесечно дете са гастричним тумором који је реципропан комбинованом лапароскопско-ендоскопском техником, након чега је постављена дијагноза гастричног шванома.

Приказ болесника Болесник је примљен на нашу педијатријску кућницу због фебрилности непознатог узрока. Након поналасних хематемеза, током гастроскопије и микроскопске анализе биле су уредени. Две недеље касније, полигонална формација у пределу антрума није је током ултрасонографског прегледа. Поновљена гастроскопија и CT потврдили су присуство туморске масе пречника 5 см. Урађена је комбинована лапароскопско-ендоскопска полипектомија са неопходном конверзијом у циљу комплетне ресекције тумора. Иницијални хистолошки резултат указивао је на гастроинтестинализни стромали тумор. Због реткоси овог тумора у дечјем узрасту, парфаксне плочице носиле су ради добијања другог мишљења. На основу хистолошка и имунохистохемске анализе у лабораторијама педијатријске патологије утврђено је да се ради о гастричном шваному који је у целости одстрањен. Није било рецидива болне током седмогодишњег праћења пацијента.

Закључак: Комбинована лапароскопско-ендоскопска ресекција могућа је и ефикасна терапија за лечење туморских лезија у зиду желуца које се не могу одстранити ендоскопски. Шваном је неопходно укључити у диференцијално-дијагностичка разматрања туморских лезија желуца, чак и у дечјем узрасту.

INTRODUCTION

Gastrointestinal (GI) schwannoma was first described in 1988 by Daimaru et al [1]. The stomach is the most common site, and gastric schwannoma (GS) represents 0.2% of all gastric neoplasms [2]. They are believed to arise from the disperse autonomic nerve Schwann cells, in contrast to much more common schwannoma of the skin, connective tissue and other internal organs that arise from peripheral nerves. These differences are also related to schwannomas’ gross and histological features in the gastric location [2]. Also, unlike peripheral schwannoma, GS is rarely associated with neurofibromatosis, so it probably has a different genetic basis [3, 4, 5]. However, the immunohistochemical characteristics of schwannomas in all locations are the same. Immunohistochemistry plays a pivotal role in distinguishing GSs from more common mesenchymal tumors in the GI tract: gastrointestinal stromal tumor (GIST), smooth muscle neoplasms and inflammatory fibroid polyp [2–5].

GS occurs predominately in adults and is more common in women. The symptoms are nonspecific and it may be detected incidentally [2, 4, 6].

Endoscopy with simultaneous resection of the lesion is highly advisable for GI lesions in mucosal and submucosal locations. Still, open or laparoscopic surgical resection has been the only available treatment in most cases of deeply sited gastric neoplasms with excellent postoperative prognosis [2, 4, 7, 8].

We present a case of a 14-month-old boy with a gastric tumor who underwent a combined laparoscopic-endoscopic resection procedure, followed by the histopathological diagnosis of GS.

This study was designed as case report and was conducted according to the guidelines of the Declaration of Helsinki. It was approved by the Institutional Review Board of the Institute for Child and Youth Healthcare of Vojvodina (No 2284 from 4th of June 2021).
CASE REPORT

The patient was admitted to our pediatric clinic with a fever of unknown origin. Clinical examination did not reveal the cause of the fever. Non-steroidal anti-inflammatory drugs were administered. After recurrent hematemesis, on the 7th day of the hospitalization endoscopy was performed which revealed a large ulcer with a diameter of 38 mm in the stomach’s antropyloric segment (Figure 1 A). Afterwards, the patient was under a clinical follow-up and was treated with pantoprazole. After a four-week follow-up, gastroscopic and microscopic findings were normal (Figure 1 B). Two weeks later, a flank mass in the antrum was found by an ultrasound examination. New gastroscopy and CT scan confirmed the presence of a well circumscribed, polypoid, submucosal tumor mass measuring 4.8 x 4.0 x 4.0 cm, lined with flattened mucosa, in the antropyloric region.

A combined laparoscopic-endoscopic resection, the so-called “rendez-vous” procedure, was performed the next day. Under general anesthesia, the endoscope was inserted, and the location and diameter of the tumor was confirmed (Figure 1 C). Then the camera port was inserted in a standard infraumbilical position using an open Hasson technique. A carbon dioxide pneumoperitoneum was established, with a pressure of 8-10 mm Hg. Two additional ports (5 mm) were inserted into the left and right upper quadrants. Firstly, a front abdominal wall gastrotomy was performed using endoscopy navigation. Then an excision of the tumor in its entirety was made. The standard laparoscopic operation was practically converted to video-assisted procedure (Figure 1 D). It means that the stomach was exteriorized through umbilical port, which was slightly enlarged, and polypectomy was performed extracorporeally. As a result, the defect remained on the back wall due to the radicality of the resection. The operation was completed with the closure of the posterior and anterior stomach wall, both with direct sutures. Finally, a nasogastric tube was placed.

Initially, the tumor which measured 5 cm in the largest diameter (Figure 1 E), was diagnosed as GIST. Due to the extreme rarity of GIST in childhood, tissue samples were sent for a second opinion (Belgrade). Tumor was composed of elongated spindle cells with mild nuclear atypia and moderate mitotic activity (15 mitoses/50 high power field). Interstitium was myxomatous with a decreased density of tumor cells. Except in the central area of the ulceration, the tumor was lined with atrophic mucosa. The tumor at the base showed infiltrative growth between the muscle propria fibres (Figure 2 A-C). After immunohistochemical staining,
tumor cells were positive for vimentin, S-100 (Figure 2 D), GFAP, focally CD34, and negative for desmin, muscle-specific and smooth muscle actin, caldesmon, calponin, CD117, DOG1, ALK-1, CK, EMA, BCL-2, CD99 and TLE-1. Histological and immunohistochemical characteristics of the tumor made the diagnosis of GIST extremely unlikely and were consistent with GS. Resection margins were tumor-free. Histological and immunohistochemical analyses were repeated by an expert team (Liverpool, UK) who agreed with the diagnosis of GS. Due to the lack of clinical criteria and negative family history, neurofibromatosis was also unlikely.

The postoperative course was uneventful. No adjuvant therapy was administered. There was no recurrence of the tumor during seven years of follow-up (Figure 1 F).

DISCUSSION

Most tumors located in the stomach above the muscularis propria can be excised endoscopically. The available techniques comprise snare polypectomy, endoscopic mucosal resection (EMR), and piecemeal EMR [9, 10]. If the tumor is located in the deeper layers, the possibility of complete resection is questionable. The optimal treatment for such tumors is an open or laparoscopic surgery [11, 12].

Laparoscopic wedge resection is being performed with increasing frequency [13, 14, 15]. In 2004, the National Comprehensive Cancer Network and The European Society of Medical Oncology published consensus statements doubting the efficacy of laparoscopic resection for GIST of the stomach [16]. In this report, laparoscopic resection is approved for GIST smaller than 2 cm. According to recent publications, many surgeons achieved complete resection (R0) laparoscopically, with no complications in terms of rupture or tumor spillage [17].

Combined laparoscopic-endoscopic techniques represent an innovative concept in the treatment of colonic and gastric lesions. The idea for this approach came from the paper of Gloria Pelizzo and Juergen Schleef published in 2007 [18]. The first procedure in our clinic was performed 13 years ago to treat a patient with familiar adenomatous polyposis syndrome. Minimally invasive “rendez-vous” surgery allows the opportunity to make an accurate histological analysis while a high level of patient comfort is maintained [19, 20].
About three-quarters of GI tract schwannoma are located in the stomach, most commonly in the area of the great curvature, following with antrum and fundus [4, 5, 6, 8]. Lauricella et al. [8] found 686 patients with GS published in the English-language literature for over 30 years. Most of the articles dealt with individual cases. Only 10% of all tumors were removed endoscopically, while an equal number of other tumors were removed by total/subtotal gastrectomy and local excision, respectively. Tumor recurrence was very infrequent and did not depend on the surgical method.

All of 221 patients with GS in the literature review of Hu et al. [6] were older than 40 years. The youngest registered patient with GS so far was a 16-year-old girl [21].

The histological features of the tumor in our patient confirm that GS histologically differs somewhat from peripheral or soft tissue schwannoma (STS). Unlike STS, GS is usually not encapsulated, lacks nuclear palisading (Verocay bodies), alternating areas of hypercellularity (Anthony A and B), vascular hyalinization and dilatation. GS often has a peritumoral cuff-like lymphocytic infiltration, microtrabecular architecture and cellular atypia [4, 6]. Mitotic activity in our tumor was at the upper limit (criteria for separation benign from malignant GS) [6]. GS is very rarely associated with neurofibromatosis 1 and 2 syndrome.

Immunohistochemical analysis remains the main diagnostic method for distinguishing spindle cell tumors, including mesenchymal tumors of the gastric wall. In our case, repeated analyses in two laboratories specialized for pediatric pathology showed negative immunohistochemical staining results with markers characteristically positive in GIST (CD117, DOG1). The key markers for schwannoma differentiation, S-100 and GFAP, were positive in this case. Also, the immunophenotype of tumor cells did not correspond to some of the very rare childhood tumors (myofibroblastic neoplasms, solid fibrous tumor, synovial sarcomas, and some types of hemangioendotheliomas).

Combined laparoscopic-endoscopic polypectomy is a feasible and effective treatment for large gastric tumors that cannot be excised endoscopically. This is a safe technique that enriches the therapeutic range of the surgeon and healthcare institution in which it is performed. This case suggests that schwannoma should be included in the differential diagnostic consideration of gastric tumor lesions even in childhood.
ACKNOWLEDGEMENT

We thank Dr. George Kokai and his colleagues from the Department of Histopathology, Alder Hey Children’s Hospital, Liverpool, UK for their great help in the histopathological diagnosis of this tumor, and Mr. Simon Belcher and Dr. Dejana Božić for the excellent photo editing.

Conflict of interest: None declared.
