Accepted papers are articles in press that have gone through due peer review process and have been accepted for publication by the Editorial Board of the Serbian Archives of Medicine. They have not yet been copy-edited and/or formatted in the publication house style, and the text may be changed before the final publication.

Although accepted papers do not yet have all the accompanying bibliographic details available, they can already be cited using the year of online publication and the DOI, as follows: the author’s last name and initial of the first name, article title, journal title, online first publication month and year, and the DOI; e.g.: Petrović P, Jovanović J. The title of the article. Srp Arh Celok Lek. Online First, February 2017.

When the final article is assigned to volumes/issues of the journal, the Article in Press version will be removed and the final version will appear in the associated published volumes/issues of the journal. The date the article was made available online first will be carried over.

Research on the influence of prenatal exercises on anthropometric and vascular parameters in pregnant women

Истраживање утицаја пренаталних вежби на антропометријске и васкуларне параметре трудница

SUMMARY

Introduction/Objective The frequency of a sedentary lifestyle during pregnancy increases. This contributes to gestational weight gain and has a negative impact on health. This study researched the impact of prenatal exercise on gestational weight gain, blood pressure, and microcirculation in pregnant women who exercised and those who did not exercise.

Methods The study included seventy pregnant women with a normal pregnancy, who attended a psychophysical preparation program for childbirth for eight weeks. The control group (n=35) attended theoretical classes on childbirth, and the experimental group (n=35) attended prenatal exercises as well. Gestational weight gain, blood pressure, and nailfold capillary density were determined and compared between the two groups.

Results Gestational weight gain of 19.94 kg in non-exercising pregnant women was significantly greater than the gestational weight gain of 11.65 kg in pregnant women who exercised. Pregnant women who did not exercise had an increase in systolic (by 15.56 mmHg) and diastolic pressure (by 16.08 mmHg), which is significantly higher compared to pregnant women who exercised. In this group, systolic pressure increased by 2.5 mmHg, while diastolic did not change. A significant difference in the nailfold capillary density at the end of the prenatal program has not been determined.

Conclusion Prenatal exercise of moderate-intensity has a positive effect on gestational weight gain and the level of blood pressure in pregnant women. The nailfold capillary density has not differed significantly after the prenatal program in pregnant women who have exercised and in those who have not.

Keywords: physical activity; pregnancy; gestational weight gain; blood pressure; microcirculation; microvessel density measurement

INTRODUCTION

The incidence of a sedentary lifestyle during pregnancy increases, ranging from 64.5% to 91.5%, and tends to increase in the third trimester of pregnancy. This contributes to the
occurrence of obesity in pregnancy, gestational weight gain (GWG), and maintaining postpartum body weight, and has a negative impact on the health of pregnant women. In recent years in Europe, the prevalence of obesity in the entire population has increased epidemically and in pregnant women is around 25% [1-5]. The American Institute of Medicine presented guidelines and recommendations for gestational weight gain. Gestational weight gain for normally fed pregnant women (body mass index - BMI 18.50 - 24.99 kg/m²), is 11.5 to 16 kg [6].

Studies have shown that pregnant women who have a sedentary lifestyle are 1.5 times more likely to gain weight during pregnancy compared to pregnant women who exercise [7,8]. However, concerns about the safety of exercise in pregnancy seem to persist. In studies, there is a large difference in interventions and exercise intensity in pregnancy [9].

Excessive weight gain during pregnancy is a risk factor for gestational diabetes and pregnancy-induced hypertension (PIH). During pregnancy, the circulatory system is largely adapted to meet the needs of the mother and fetus [10,11]. In a normal pregnancy, blood pressure gradually increases during the second and third trimesters, while peripheral vascular resistance decreases, resulting in maintaining blood pressure values in the normal range. Pregnant women who do not exercise are three times more likely to develop hypertension compared to those pregnant women who exercise [10-15]. There is little data on the effect of exercise in the prenatal period on circulatory characteristics in normal pregnancy. This study researched the effect of prenatal exercise on gestational weight gain, blood pressure, and microcirculation in pregnant women who exercised regularly, compared to pregnant women who did not exercise regularly.
METHODS

The prospective, randomized study included seventy pregnant women (n = 70) in the northern part of Bosnia and Herzegovina. The study was performed at the university setting of the University of Banja Luka, Faculty of Medicine, and at the Health center “Sveti Vračevi Čelinac”, from December 2020. to August 2021. Trial registration: Clinicaltrials.gov identifier - NCT05001906. At the gynecological appointment a healthy singleton pregnant women, confirmed by a gynecologist, were assigned to the control and experimental group with a simple randomization process using a list of random numbers. Respondents, aged 20 to 40 years, with BMI < 25 kg/m², joined the birth preparation program from the 20th to the 32nd week of gestation. BMI before pregnancy was determined by dividing body weight in kilograms by squared body height in meters (kg/m²), [16]. Respondents who agreed to participate in the research voluntarily signed an informed consent form. The Ethics Committee of the Faculty of Medicine in Banja Luka approved the study.

Pregnant women were excluded from the study if bleeding appeared during the prenatal program in the second or third trimester, rupture of the amniotic sac, preeclampsia or pregnancy-induced hypertension, and intrauterine growth restriction (IUGR) in the current pregnancy, anemia.

The prenatal program lasted for eight weeks and consisted of theoretical classes on childbirth and prenatal exercises. The control group (n = 35) attended theoretical classes three times a week, and the experimental group (n = 35) attended prenatal exercises, as well. According to ACOG recommendations (American College of Obstetricians and Gynecologists) a prenatal exercise program was created to improve the condition of the pregnant woman, strengthen the extremities, the area of the abdomen, back, pelvic girdle and improve circulation [6]. Breathing exercises were conducted. During the research, pregnant women followed the general recommendations of exercise: they did not exercise additionally.
in other places, ate normally, dressed in light, and avoided high heat, the room temperature of the exercise room did not exceed 24 °C. Pregnant women exercised three times a week for 45 minutes. The exercise program was conducted by the prenatal instructor and supervised by a physiatrist. Training started and ended with breathing and relaxation techniques for about 10 min, warm-up consisted of moderate walking for about 5 min, followed by strength and stretching exercises for about 30 min. Pregnant women exercised in standing, sitting, kneeling, and sideways position, with or without props (balls, straps, weights, etc.). Exercises performed in a supine position with bent knees during this study did not last more than 5 min, thus avoiding the reduction of venous flow and hypotension [6]. The exercises were performed alone or in pairs, with another pregnant woman or partner, in two to three sets, with ten to twelve repetitions.

At the beginning and end of the study gestational weight gain, blood pressure, and nailfold capillary density were analyzed. The blood pressure was measured using a standard mercury manometer before prenatal exercises, at the beginning (between 20 and 32 weeks of gestation), and after eight weeks of prenatal exercises (between 28 and 40 weeks of gestation).

During prenatal exercises, the exercise load of pregnant women was monitored based on the subjective feeling of load using the Borg rate of perceived exertion scale. The applied physical activity was of medium intensity for which the score of perceived effort should be 13–14 (moderately difficult) out of a total of 6–20. The range of 6 to 20 is actually an analogy with the resting heart rate (60) and at maximum load (200), [2]. Pregnant women were explained that when they subjectively felt "moderately difficult" they should stop doing the exercise. It was also used "talk test". It is believed that as long as a pregnant woman can talk during exercise, she is probably not overburdened or tired [7].
In this study, nailfold capillaroscopy was performed with a Leica Z4 stereomicroscope and a digital camera. Pregnant women sat with their left hand placed on a table at heart level and a drop of immersion oil was placed on the nailfold in order to improve the image resolution. The density of capillary loops of the nailfold was assessed as the number of capillary loops per 1 mm of the distal row of nailfold capillary. Nailfold capillary loops of the fourth finger of the left hand of all pregnant women were analyzed. The morphometry of the nailfold capillaries was performed using Image Y software.

Statistical analysis was performed with the use of the licensed version of the SPSS 20 software. The obtained data were analyzed by methods of descriptive statistics. The t-test for paired samples, with the appropriate level of significance p < 0.05, was used to test the significance of the difference between the two arithmetic means.

RESULTS

The control and experimental groups were equalized in relation to the life age, the gestational age, and the BMI of the pregnant women before pregnancy (Table 1).

In the control group after 8 weeks of attending theoretical classes on childbirth, the GWG was 19.94 ± 3.37 kg (mean value ± standard deviation, MV ± SD), (Figure 1). The smallest weight gain in this group was 13 kg and the largest 29 kg. In the experimental group, after eight weeks of attending prenatal exercises, the GWG was 11.65 ± 1.35 kg (Figure 1). The smallest weight gain in this group was 9 kg and the largest 15 kg.

Using a t-test, a significant difference in the increase in GWG was found between pregnant women who did not exercise (MV=19.94, SD=3.37) and pregnant women who exercised (MV=11.65, SD=1.35), (t=13.658, p<0.001). The difference in GWG (MV=8.30) between the two groups of pregnant women is large (eta square = 0.70). Pregnant women who did not exercise had significantly higher GWG.
In the control group, at the beginning of the theoretical classes on childbirth, systolic blood pressure was 111.67 ± 9.41 mmHg (Table 2). The lowest recorded value of systolic blood pressure was 90 mmHg, and the highest value was 120 mmHg. At the end systolic blood pressure was 127.22 ± 13.44 mmHg. The lowest recorded value was 90 mmHg, and the highest value was 150 mmHg, which is a hypertensive value. Four pregnant women developed hypertension. A significant large difference was found in the systolic blood pressure determined in the first measurement time and the second measurement time (t = -8.241, p <0.001; eta square = 0.66), (Table 2). The increase in systolic blood pressure in the control group was 15.56 mmHg (Figure 2).

In the control group at the beginning of the theoretical classes, diastolic blood pressure was 71.11 ± 7.85 mmHg (Table 2). The lowest recorded value of diastolic blood pressure was 60 mmHg, and the highest value was 80 mmHg. At the end of the classes, diastolic blood pressure was 87.19 ± 17.97 mmHg. The lowest recorded value was 60 mmHg, and the highest value was 110 mmHg. There is a significant large difference in diastolic blood pressure found in the first and second measurement time (t = -4.857, p<0.001; eta square=0.40). The increase in diastolic blood pressure in the control group was 16.08 mmHg (Figure 2).

In the experimental group at the beginning of prenatal exercise, systolic blood pressure was 108.68 ± 9.79 mmHg (Table 2). The lowest recorded value of systolic blood pressure was 90 mmHg, and the highest value was 130 mmHg. At the end of prenatal exercise, systolic blood pressure was 111.18 ± 9.77 mmHg. The lowest value of systolic blood pressure was 90 mmHg, and the highest value was 130 mmHg. In the experimental group there was a significant increase in systolic blood pressure (mean difference = 2.50 mmHg) with systolic pressure remaining within normal limits, that is hypertension did not develop (t = -2.153, p = 0.039). The difference is of medium intensity (eta square = 0.12), (Figure 2). In
the experimental group, it was observed that some pregnant women had to slow down with exercise because they felt tired and weak.

In the experimental group, at the beginning of exercise, the mean value of diastolic blood pressure was 68.38 ± 9.43 mmHg (Table 2). The lowest determined value of diastolic blood pressure was 60 mmHg, and the highest was 80 mmHg. At the end of exercise, diastolic blood pressure was 68.24 ± 8.25 mmHg (Table 2). The lowest recorded value was 60 mmHg, and the highest value was 85 mmHg. A significant difference in the mean value of diastolic blood pressure in the first and second measurement time was not found (t = 0.144, p = 0.887). Diastolic blood pressure was within normal limits (Figure 2).

In pregnant women who exercised, the increase in systolic blood pressure of 2.50 mmHg was significantly less compared to the increase in systolic blood pressure of 15.56 mmHg in pregnant women who did not exercise (t = -5.892, p = 0.0001) (Figure 2). In pregnant women who exercised, there was no significant increase in diastolic blood pressure after eight weeks of follow-up, while in non-exercising pregnant women there was an increase in diastolic blood pressure of 16.08 mmHg, which is a significant difference (p<0.0001), (Figure 2).

The density of nailfold capillary loops was analyzed. Nailfold capillary loops had a hairpin shape and were organized in rows (Figure 3). In non-exercising pregnant women nailfold capillary density was 7.29 ± 1.21 capillaries/mm at the beginning of the study and 7.29 ± 0.98 capillaries/mm at the end of the study (Table 3). The nailfold capillary density in non-exercising pregnant women did not change after eight weeks of gestation (p<0.001).

In pregnant women who exercised nailfold capillary density was 7.05 ± 1.36 capillaries/mm at the beginning of the study and 7.05 ± 1.36 capillaries/mm at the end (Table 3). The density of nailfold capillary loops in pregnant women who exercised did not change after eight weeks of pregnancy (p<0.001).
DISCUSSION

In this study pregnant women who exercised had significantly less GWG. A study by Vargas-Terrones and co-authors showed that prenatal exercise and diet during pregnancy reduced GWG [8]. Non-exercising pregnant women were 1.5 times more likely to gain weight during pregnancy [15]. da Silva and co-authors found that an exercise program reduced GWG [9]. In pregnant women different types of prenatal exercises have reduced GWG [17]. Multiple factors can affect GWG, including type and/or intensity of exercise, lifestyle, diet, lifestyle alignment, and socioeconomic and environmental factors [8]. Weight gain is caused by an imbalance between energy intake and energy spending. In this study, pregnant women who exercised, ate normal, but did not have a sedentary lifestyle and therefore had higher energy spending. The weight of pregnant women during the prenatal program can be controlled and possible complications for the health of the mother and baby can be prevented.

Weight gain increases the risk of developing hypertension during pregnancy. Blood pressure gradually increases during the second and third trimesters [14]. Physical activity may reduce the risk of developing hypertensive disorders and functional status depends on individual patient performance [18-20].

In this study, at the end of theoretical classes, non-exercising pregnant women had a significant increase in systolic blood pressure of 15.56 mmHg, and diastolic blood pressure of 16.08 mmHg. In pregnant women who exercised, a significant increase in systolic blood pressure of 2.50 mmHg was found, and diastolic blood pressure did not change significantly.

In pregnant women who exercised, the increase in systolic blood pressure after eight weeks of 2.50 mmHg was significantly less than the increase in systolic blood pressure in non-exercising pregnant women. In pregnant women who exercised, there was no significant increase in diastolic blood pressure after eight weeks of follow-up, which is a significant
difference compared to non-exercising pregnant women in whom there was an increase in
diastolic blood pressure of 16.08 mmHg.

In pregnant women who exercise there were improvements in blood pressure [15, 21].
Boparai and co-authors showed that pregnant women who exercised, showed after
intervention an attenuated increase in arterial pressure compared to the control group [14].
Pregnant women who have not exercised are three times more likely to develop hypertension
compared to pregnant women who have exercised [15,21]. The potential reason why pregnant
women who exercised had a lower systolic and diastolic blood pressure increase than the
non-exercising pregnant women, could be the beneficial effects of exercise in the prevention
of excessive gestational weight gain. Obesity is associated with hypertension. Weight gain
leads to an increased risk of developing hypertension during pregnancy. Pregnancy is a
unique opportunity to improve health outcomes for both mother and child. Physical activity
in pregnancy had beneficial effects on anxiety and blood pressure [22-24].

During pregnancy, the macrocirculation and microcirculation of pregnant women adapt.
Data on the microcirculatory adaptation of pregnant women are scarce, mostly due to
technical limitations [10].

In this study, the density of nailfold capillary loops in non-exercising pregnant women
and those who exercised did not change after eight weeks of pregnancy. The average density
of nailfold capillary in non-exercising pregnant women, at the beginning of the study was
7.29 capillaries/mm, and at the end was 7.29 capillaries/mm. The density of nailfold capillary
in pregnant women who exercised at the beginning of exercise was 7.05 capillaries/mm, and
at the end 7.05 capillaries/mm.

In studies, the average capillary density ranges from 7.3 to 10.3 capillaries/mm in
healthy adults [25-27]. In previous research during pregnancy was observed an increase in
capillary density and neoangiogenesis, and a reduction in capillary dilations [10]. Monitoring
of microcirculatory changes can be viewed as a method that helps us to record the changes that precede the onset of clinical disease. Decreased capillary density has been demonstrated in individuals with hypertension [28]. Studies have revealed that the method of nailfold capillaroscopy facilitates the identification of women who have a more pronounced tendency to pregnancy-induced hypertension because of the structural rarefaction of capillaries. In the control group, where a significant increase in blood pressure was found after eight weeks of follow-up, there was no decrease in capillary density. It is possible that the increase in blood pressure is reflected more in other characteristics of nailfold capillaries, such as the shape or length of capillaries, and further research is needed.

The described birth preparation program was developed for the purpose of promoting physical activity during pregnancy as a healthy lifestyle, reducing anxiety, and improving the self-control of pregnant women in childbirth.

Identifying risk factors for future cardiovascular diseases and early assessment of the circulatory status of pregnant women can lead to earlier lifestyle changes and disease prevention.

CONCLUSION

Prenatal exercise of moderate-intensity has a positive effect on gestational weight gain. Pregnant women who did not exercise had a significantly greater increase in gestational weight gain. Prenatal exercise of moderate-intensity has a positive effect on blood pressure. In pregnant women who exercised, the increase in blood pressure was less compared to the increase in blood pressure in pregnant women who did not exercise. After eight weeks of the prenatal program, the difference in the capillary density of the nailfold was not determined in pregnant women who exercised and pregnant women who did not exercise.
