*Accepted papers are articles in press that have gone through due peer review process and have been accepted for publication by the Editorial Board of the Serbian Archives of Medicine. They have not yet been copy-edited and/or formatted in the publication house style, and the text may be changed before the final publication. Although accepted papers do not yet have all the accompanying bibliographic details available, they can already be cited using the year of online publication and the DOI, as follows: the author’s last name and initial of the first name, article title, journal title, online first publication month and year, and the DOI; e.g.: Petrović P, Jovanović J. The title of the article. Srp Arh Celok Lek. Online First, February 2017. When the final article is assigned to volumes/issues of the journal, the Article in Press version will be removed and the final version will appear in the associated published volumes/issues of the journal. The date the article was made available online first will be carried over.

A case report of a hybrid procedure (visceral and partial aortic arch debranching) in the treatment of a challenging aneurysm of the thoracoabdominal aorta in the endovascular era

SUMMARY

Introduction This paper aimed to present a hybrid approach as less invasive and acceptable treatment.

Case outline Because of respiratory failure, the patient was deemed at high risk for open repair. Standard thoracic endovascular aortic repair (TEVAR) was unfeasible, so the patient underwent the hybrid procedure - partial aortic arch debranching in a first stage followed by visceral debranching and endovascular exclusion of thoracic aortic aneurysm as a final procedure. The postoperative course was uneventful and the patient was discharged 10 days after TEVAR and visceral debranching.

Conclusion Staged hybrid procedure with combined debranching of the aortic arch and visceral arteries is feasible and should be considered as an alternative treatment option in patients with high-risk for open repair.

Keywords: endovascular procedure; aortic aneurysm; dissecting aneurysm

INTRODUCTION

Hybrid treatment with visceral and arch vessel debranching followed by thoracic endovascular aortic repair (TEVAR) has been used to treat high-risk patients and therefore allows treatment in this population group [1, 2, 3]. This paper aimed to present a hybrid approach as less invasive and acceptable treatment.

CASE REPORT

A 56-year-old male was admitted to our hospital due to chronic dissecting aneurysm of the thoracic aorta with a maximum diameter of 8 cm (Figure 1). Visceral and infrarenal part
of the abdominal aorta was free of dissection and aneurysmal disease. A few years ago, he suffered acute aortic dissection. Considering coexisting chronic obstructive pulmonary disease (forced expiratory volume in first second - FEV1 was 50 %), the patient was high risk for open repair. Multidetector computed tomography with angiography (MDCTA) imaging showed that standard TEVAR was unfeasible because of inappropriate characteristics of proximal and distal sealing zone, so staged hybrid procedure was selected. Partial debranching of the aortic arch and visceral arteries provided an adequate length of both sealing zones of 25mm. To achieve adequate proximal sealing zone for stent-graft deployment in the Ishimaru zone 1 of the aortic arch, we performed extrathoracic paratracheal carotid-carotid bypass in a right-to-left manner in conjunction with carotid-subclavian bypass using 8mm tubular Dacron graft. After the transverse section of the left common carotid artery, the proximal part was ligated while the distal part was anastomosed to the Dacron graft in an end-to-side fashion. The end-to-side anastomosis was also created to the left subclavian artery. We always endeavor to ligate the subclavian artery. However, in this case, the prevertebral part of the subclavian artery was difficult to approach. The left subclavian artery was originated from the proximal landing zone, 12mm away from the entry tear. Hence, it was expected that stent-graft would cover the artery origin preventing the endoleak from the left subclavian artery. Otherwise, endovascular occlusion of the artery would have been indicated. The procedure was performed under general anesthesia. The carotid shunt was not used because the retrograde flow from common carotid arteries was pulsatile. The postoperative course was uneventful, so two days later we performed visceral debranching via the midline laparotomy. The right common iliac artery was selected as an adequate inflow vessel for visceral debranching. CT revascularization was accomplished via by-pass to the common hepatic artery (CHA) in an end-to-side fashion. Celiac trunk (CT) and CHA were approached through the gastrohepatic ligament in the lesser sac, while superior mesenteric artery (SMA) was identified at the base of the transverse mesocolon proximally to the origin of the middle colic artery. We used a jump graft (tubular Dacron graft of 8 mm) from the SMA to CHA. The graft was passed retroperitoneally from the right common iliac artery to the SMA and then behind the pancreas to the CHA. CT and SMA were ligated after completion of the bypass to avoid retrograde filling of the aneurysm sac. TEVAR was performed immediately after visceral debranching via the left transfemoral approach (Figure 2).
The thoracic aortic aneurysm was excluded using three Valiant Thoracic Stent Graft (Medtronic Vascular, Santa Rosa, CA) deployed above the renal arteries upwards to the innominate artery using the distal-to-proximal implantation technique which enables the deployment of a larger diameter stent-graft into a smaller diameter graft. Oversizing at the proximal and distal landing zone was 10-15%. To prevent paraplegia cerebrospinal fluid drainage was used during the following 72 hours to maintain an intrathecal pressure below 10 mmHg and mean arterial pressure was targeted at ≥ 80 mm Hg. The postoperative course was uneventful and the patient was discharged home 10 days after TEVAR and visceral debranching. After 5 years follow-up MDCTA showed the regular position of the stent-graft and regular patency of the supra-aortic and visceral debranching (Figure 3).

DISCUSSION

In this paper, we report a case with a chronic dissecting thoracic aortic aneurysm who successfully underwent hybrid procedure. In terms of age and respiratory comorbidity, our patient was considered high risk for conventional open repair of a thoracic aortic aneurysm which would require thoracophrenolombotomy, single-lung ventilation, and aortic crossclamping. A less invasive hybrid approach was indicated as an acceptable treatment. Its theoretical advantages implicate avoiding extensive two-cavity exposure, aortic crossclamping, and extracorporeal circulation. Dissecting aortic aneurysm involved the thoracic part from the left subclavian artery to the CT. In order to achieve the adequate length of sealing zones and endograft apposition to the inner aortic curvature, partial arch debranching and retrograde bypass to the CT and the SMA were necessary. We decided for two-stage hybrid treatment. Extra-thoracic partial debranching of the aortic arch was performed as a first procedure. We used pretracheal route for crossover right-to-left carotid-carotid bypass, which we considered easier for tunneling and with more space for anastomosis creation. Other authors prefer the retropharyngeal route as a shorter and more direct path across the neck [4]. Also, in elective cases in whom left subclavian artery is going to be covered by endograft, we always perform left carotid to subclavian artery bypass to prevent spinal cord ischemia, stroke, and arm claudication. Visceral debranching did not include renal arteries revascularization, so TEVAR was performed during the same procedure. In cases that required renal arteries clamping and revascularization, some authors recommend that TEVAR should be performed few days after visceral debranching to allow the kidneys to
recover from the ischemia associated with the bypass before subjecting them to the nephrotoxic iodinated contrast during TEVAR [5]. Because of extensive coverage of thoracic aorta, our patient was deemed as a high risk for spinal cord ischemia, hence prophylactic cerebrospinal fluid drainage was used as recommended by current guidelines of the European Society for Vascular Surgery [6].

Instead of hybrid procedures, in some institutions total endovascular repair is possible using custom-made and physician-modified fenestrated and branched devices as well as parallel graft techniques (chimney/periscope).

Published mid-term results of endovascular renal and visceral artery revascularization are encouraging. Recently published studies showed a high technical success rate of 94–96% and primary 5 years visceral arteries patency of 93% after fenestrated and branched endografts, but in the same period, reinterventions were necessary in half of the cases [7, 8]. Also, Tsilimparis et al. [7] showed favorable outcomes of this technique, which is associated with lower mortality and morbidity (acute renal failure and mesenteric ischemia) in comparison to the hybrid procedure. High device costs and long manufacturing of custom-made fenestrated and branched devices limit this technique in cases with huge and symptomatic aneurysms. Also, these devices are not available in many centers from developing countries. Alternative “off the shelf” endovascular techniques, like parallel graft techniques and physician modified fenestrated stent-grafts, involve the use of standard grafts with good short-term and mid-term results [9–15]. Considering the anatomy of our case, we deemed that the diameter and shape of true lumen were inadequate to accommodate two chimney grafts for CT and SMA. Furthermore, we assessed that periscope graft in these arteries would be associated with acute angulation and risk for thrombosis.

Fenestrated stent-grafting in aortic arch is technically challenging due to difficulties in stent-graft orientation and fenestration positioning. In situ fenestration techniques might avoid these problems, but because of possible issues with stent-grafts durability and ischemic complications during temporary carotid arteries coverage, this technique has not been widely adopted [16-18]. In recent years, arch branched endografts have been developed as a new technique for revascularization of supra-aortic branches. Despite encouraging initial results further studies are required to standardize this technique [19, 20, 21]. Chimney technique to extend the proximal landing zone in TEVAR is feasible in majority vascular centers with satisfied midterm outcomes but not without risk of major complications [22–25]. Zhao et al.
compared the outcomes of the chimney and hybrid technique for the reconstruction of a single arch branch and found that type Ia endoleak rate was significantly higher in the chimney group [26]. Supra-aortic branch angulation and excessive oversizing were determined as a major risk factor for type Ia endoleak. Furthermore, compression and fracture of chimney graft, as well as retrograde type A aortic dissection, can lead to lethal consequences [27, 28]. Frequently performed excessive oversizing and ballooning of endografts, as well as more than one chimney graft carries the greatest risk for retrograde dissection. In our institution, fenestrated and branched endograft techniques are not an option for aortic repair yet. Although the problem of the proximal landing zone in our case could be resolved by two chimney grafts for the left subclavian and common carotid artery, we did not consider this technique because of abovementioned reasons.

In selected cases of difficult aortic arch anatomy and risk for retrograde type A dissection after TEVAR, a frozen elephant trunk can be an alternative method for arch repair [29]. Sometimes, when the aortoiliac segment is not suitable for inflow, antegrade visceral debranching from ascending aorta might be performed [30].

Staged hybrid procedure with combined debranching of the aortic arch and visceral arteries is feasible and should be considered as a treatment option in patients with high-risk for open repair.
